CHAPTER 1—INTRODUCTION AND SCOPE

1.1—Introduction
Concrete is the most widely used construction material in the world. The design, detailing, and execution of concrete to resist weathering action, chemical attack, abrasion, and other processes of deterioration over its intended service life will determine its durability. Durable concrete will retain its original form, quality, and serviceability when exposed to its environment. Properly designed, proportioned, transported, placed, finished, and cured concrete can provide decades of service with little or no maintenance, yet certain conditions or environments exist that can lead to concrete deterioration. Deterioration mechanisms are either chemical or physical in nature and may originate from within the concrete, or may be the result of the external environmental exposure. Chemical and physical attacking mechanisms often work synergistically. Depending on the nature of the attack, distress may be concentrated in the paste, aggregate, or reinforcing components of the concrete, or a combination thereof.

The various factors influencing durability and a particular mechanism of deterioration should be considered in the context of the environmental exposure of the concrete. In addition, consideration should be given to the microclimate to which the specific structural element is to be exposed. The type and severity of deterioration of a given structure may be affected by its proximity to sources of deleterious agents or agents that facilitate distress, exposure to wind, precipitation, or temperature. For instance, exterior girders in a bridge structure may be exposed to a more aggressive environment than interior girders.

The concept of service life is increasingly used for the design of new structures. To produce concrete suitable for a particular application, required service life, design requirements, and expected exposure environments, both macro and micro, should be determined before defining the necessary materials and mixture proportions.

The use of good materials and proper mixture proportioning will not, by itself, ensure durable concrete. Appropriate placement practices and workmanship are essential to the production of durable concrete. Fresh concrete can be consolidated and molded to the shape desired to serve its intended purpose. During this stage, numerous properties significantly influencing the durability of the hardened concrete are established. Pore structure development, air-void system formation, material uniformity, and potential for cracking are established at early ages and are important to the ultimate durability of concrete. As such, durable concrete requires the application of good quality control during construction. Inspection and testing by trained and certified...
personnel can help ensure the use of durable mixtures and proper practices.

### 1.2—Scope
This guide discusses the important mechanisms of concrete deterioration and gives recommendations on how to mitigate or minimize such damage. This guide also addresses durability by first discussing the importance of mass transport and then addressing specific modes of attack in separate chapters. These include freezing and thawing, alkali-aggregate reaction (AAR), sulfate attack, aggressive chemical attack, physical salt attack, corrosion of metals and other embedded materials, abrasion, or a combination of these. Fire resistance of concrete and cracking are not addressed directly. Fire resistance is covered in ACI 216.1 and cracking is covered in ACI 224R and ACI 224.1R. While cracking does impact the durability of concrete in severe exposures, the different causes of cracking and their specific impacts are not discussed. Cracking is only mentioned in general terms regarding its impact on fluid ingress.

### CHAPTER 2—DEFINITIONS

#### 2.1—Definitions
Please refer to the latest version of ACI Concrete Terminology for a comprehensive list of definitions. Definitions provided herein complement that resource.

- **advective transport**—transfer of heat or matter via the bulk motion of a fluid.
- **alkali loading (or content)**—total amount of equivalent alkalis (Na₂O₄) in a concrete mixture expressed as mass per volume.
- **calcium sulfoaluminate cement**—product obtained by pulverizing clinker containing mainly ye′elimite [Ca₆(AlO₂)₃SO₄] that is often used in expansive cements and ultra-high-early-strength cements.
- **diffusion**—movement of species, such as ions, gas, or vapor, from an area of higher concentration to an area of lower concentration, independent of the bulk motion of a fluid.
- **electrical migration**—transport of electrons or ions due to an electric potential gradient.
- **ice lens**—layer of ice, generally parallel to the exposed surface of the concrete, that can produce internal damage and also lead to scaling or delamination.
- **leaching**—dissolution and removal of soluble components such as calcium hydroxide from concrete.
- **permeability**—the ability of a given concrete to permit liquids or gases to pass through.
- **permeation**—flow of a liquid, gas, or vapor within a solid under the action of a pressure gradient.
- **physical salt attack**—mechanism in which concrete or mortar is damaged as a result of salt crystallization pressure.
- **reactive silica**—form of silica, often amorphous or crypto-crystalline, that dissolves when in contact with concrete pore solution having a sufficiently high concentration of hydroxyl ions.

**salt weathering**—form of deterioration most commonly observed in arid climates where exposure to soluble salts and cyclic variations in temperature and relative humidity can lead to salt crystallization.

**thaumasite**—silicate mineral, colorless to white prismatic hexagonal crystals typically as acicular radiating groups, with the chemical formula \( \{[\text{Ca}_3\text{Si(OH)}_c\cdot 12\text{(H}_2\text{O})]\text{(SO}_4\text{)(CO}_3\}) \).

### CHAPTER 3—MASS TRANSPORT

#### 3.1—Introduction
Concrete is a multiphase porous medium consisting of a multiscale porous cement paste matrix with aggregate inclusions. Liquid and gas may be present in any pores and micro-cracks. As such, it is susceptible to the ingress and movement of substances (fluids or ions) from its environment within and through its pore system. This chapter discusses the transport of gases, liquids, and ions in solution through concrete (Lichtner et al. 1996; Baer 1988; Hearn et al. 2006; Hall and Hoff 2012). Methods for improving the durability of concrete and some of the common test methods used to measure the transport properties, along with their advantages and limitations with regard to assessing concrete durability, are also discussed. It is recognized that the rate of ingress of fluids and ions will increase by the presence of cracks. However, the specific influences of different types of cracks and crack widths are not discussed herein.

The ingress of gases, liquids, or ions in solution through concrete may initiate chemical processes, physical processes, or both, that affect the durability of the concrete under a given set of service conditions. Water itself may be harmful because of its ability to leach calcium hydroxide (CH) from the hardened cement paste and because of osmotic pressures generated as water flows to sites of higher alkalinity (Powers et al. 1954; Powers 1975; Helmuth 1960b,c). In addition, water may also be acidic or carry harmful dissolved chemicals, such as chlorides or sulfates, into the concrete. The ingress of gases such as oxygen and carbon dioxide through the concrete pores can contribute to the corrosion of steel reinforcement.

Different substances may interact with components of the concrete in different ways; therefore, transport of a substance through concrete is unique to that substance. For example, water can hydrate previously unhydrated cement particles or leach calcium. Chloride ions may be bound by the hydration products of cement or supplementary cementitious materials (SCMs). The size of the molecules or ions that are transported through the concrete, viscosity of the fluid, valence of the ions, and other ionic species present also affect the transport properties. Thus, permeability and diffusivity must be expressed in terms of the substance that is migrating through the concrete. In general, concrete with transport properties that limit the rate of ingress of external agents is not immune to chemical deterioration, but the effects are mainly near the exposed surfaces, so the concrete tends to be more durable.
3.2—Transport processes in nonreactive porous media

This section provides a brief overview of the transport processes of fluids (gases and liquids) and ions in solution within a nonreactive porous medium. This is a simplifying assumption because concrete changes chemically and physically with time in response to its environment. Physical changes, chemical changes, or both, in the internal structure of the porous medium resulting from interactions with the migrating fluids or ions are not discussed herein. The transport pathways described here include:

(a) Transport by permeation
(b) Advective transport
(c) Hydrodynamic dispersion
(d) Diffusion within the pores
(e) Transport due to electrostatic interactions or electrical migration

Martín-Pérez et al. (2001) modeled transport related to corrosion of reinforcement in concrete based on chloride transport, moisture diffusion, heat transfer, and oxygen transport using a two-dimensional (2-D) finite element model. They used a modified version of Fick’s second law.

Johannesson (2003) developed a theoretical model for diffusion of different types of ions in concrete pore solution. The model incorporates diffusion caused by concentration gradients of ions (for example, due to drying), internal electrical potential, convection, effects of changes in moisture content, and mass exchange of ions between solution and solid hydration phases.

Chung and Consolazio (2005) developed a finite difference model to simulate heat and mass transport in rapid heating conditions, such as fires in reinforced concrete structures. The model accounts for the interference between liquid and gas phases, slip-flow effects in steam flow, and the interference of steel reinforcement in moisture movement in concrete.

3.2.1 Transport by permeation—Permeation is the flow of a fluid under the action of a pressure gradient. Permeability is the property that characterizes the ease with which fluid passes through a porous material under a pressure gradient. For a steady laminar flow through a saturated porous medium, the fluid flow is related to the hydraulic pressure gradient according to Darcy’s law.

\[
\frac{dq}{dt} = K_1 A \frac{\Delta h}{l}
\]

(3.2.1)

where \(dq/dt\) is the flow (expressed as a rate); \(K_1\) is the permeability coefficient; \(A\) is the cross-sectional area; \(\Delta h\) is the hydraulic head; and \(l\) is the thickness of the specimen. The permeability coefficient \(K_1\) is the rate of discharge of water under laminar flow conditions through a unit cross-sectional area of a porous medium under a unit hydraulic gradient and standard temperature conditions. Darcy’s law indicates that for a given cross-sectional area and permeability coefficient, the flow is proportional to the hydraulic gradient \(\Delta h/l\). Under service conditions, flow is three-dimensional, and the concrete may not be saturated. In concrete, the permeability coefficient may change with increased hydration, cracking, or changes in the pore structure due to various physical and chemical processes.

Permeability coefficients of plastic portland cement pastes of 0.5 water-cement ratio (w/c), calculated from measurements of bleeding, ranged from 5 to \(8 \times 10^{-7}\) m/s for four cements with different chemical composition but the same specific surface (180 m\(^2\)/kg by the Wagner turbidimeter). The permeability coefficient of mature paste (for example, at greater than 28 days of age) is between 1 millionth and one 10 millionth of that of fresh paste. It ranges from \(1 \times 10^{-15}\) to \(1.2 \times 10^{-12}\) m/s for w/c ranging from 0.3 to 0.7 (Powers et al. 1954).

To understand the effects of microstructure on the permeability of concrete, Bentz et al. (1999) at the National Institute of Standards and Technology (NIST) used percolation theory. One useful application of percolation theory is the examination of the time needed for a material to progress through a complex maze (Stauffer and Aharony 1992). This maze consists of areas that can allow free movement, as well as areas that impede the transport of a fluid to different degrees. These models can be made in two and three dimensions and can include the effects of cracks. Lu et al. (2012) were able to use a three-dimensional version of the NIST model to predict chloride ingress into cracked concrete.

Work has also been done by NIST that models changes in the properties of these systems with time. This allows the change in the microstructure of the concrete to be examined with time and observe the effects on the ability of a fluid to move through the system.

A graphical representation of a simple percolation theory model used to model the permeability of concrete.
